Abstract
In this article, we present a re-implementation of a simple unsupervised parser introduced by Søgaard (2012). This parser is able to parse sentences without any training. Furthermore, we propose various extensions to this parser. We evaluate the impact of several extensions on six languages. While we observe some improvements, different extensions impact different languages differently and we cannot give language-independent recommendations.

1 Introduction
Syntactic dependency parsing is a major preprocessing step needed for most applications and tasks in natural language processing like question answering (Hirschman and Gaizauskas, 2001), machine translation or similarity computations, e.g. (Levy and Goldberg, 2014; Weeds et al., 2004; Curran and Moens, 2002). However, most available dependency parsers are based on supervised machine learning algorithms, which need to be trained on manually created data. In addition, the creation of such training data is time-consuming and larger treebanks are not available for many languages.

In Riedl et al. (2014) several unsupervised dependency parsers have been extrinsically evaluated by using them as context representations for computing distributional similarities. In this work, the unsupervised parser by Søgaard (2012) yielded the second best results while being the fastest parser. In contrast to the other unsupervised dependency parsers, it does not require any training on raw text and is able to perform the parsing sentence-wise as opposed to whole-corpus parsing.

Whereas some unsupervised dependency parsers, e.g. Klein and Manning (2002), have been optimized and extended, e.g. Gillenwater et al. (2010), no further extensions have been proposed to many other unsupervised dependency parsers.

As the parser introduced by Søgaard (2012) is very basic in its heuristics, we will investigate whether integrating further features can improve its parsing performance. For this, we consider using semantics and Multiword Expressions (MWEs). Additionally, we re-run the parsing and train a supervised parser based on the output of the unsupervised parser.

2 Related Work
One of the first unsupervised syntactic dependency parsers that outperformed a random baseline was introduced by van Zaanen (2001) and uses an alignment-based learning approach. This algorithm is based on comparisons of sentences and uses sequence regularities in the corpus as constituents. A more sophisticated algorithm was presented by Klein and Manning (2002) that is based on an EM approach, which uses the linguistic phenomenon that long constituents often have shorter representations of the same grammatical function when they occur within a similar context. A combination of the work of Klein and Manning (2002) with a dependency model was presented by Klein and Manning (2004), which is called Dependency Model with Valence (DMV). This approach was the first one that outperformed the right branching baseline. Due to these results, this model has been extended by using lexical information (Headden III et al., 2009) and adding posterior regularizations in the training process (Gillenwater et al., 2010). These approaches require training, based on raw text or POS-tagged text. In contrast the method introduced by Søgaard (2012) does not require any training and can be applied with and without POS information.

Information about Multi-word Expressions (MWEs) has been shown to be beneficial for supervised dependency parsers. Le Roux et al. (2014) showed that for French, the detection of MWEs improves the parsing performance. Similarly, Eryiğit
et al. (2011) demonstrated that predicting Multi-word Expressions (MWEs) and using such information for training a parser increases the performance.

3 Søgaard’s Parser

In this paper we extend the unsupervised parser introduced in Søgaard (2012). It operates on single sentences and has three stages. First, tokens are ranked according to their valency. This is achieved by creating a multigraph with the sentence’s tokens as its nodes. Edges are added following these heuristics:

- add pairwise edges to any neighbor in 1-step vicinity
- add pairwise edges to any neighbor in 2-step vicinity
- add an edge to a function word (determined by a word list) from any 1-step neighbor. The function word list is generated in advance using a simplification of TextRank (Mihalcea and Tarau, 2004) without stopword removal. The method is applied to the training data and we extract the top 50 words.
- add an edge to the verb from every other token in the sentence
- add pairwise edges between any tokens for which the 3-letter-prefix does not match
- add pairwise edges between any tokens for which the 3-letter-suffix does not match

Then, PageRank (Brin and Page, 1998) is applied in order to rank the nodes. The tokens are sorted in descending order to their rank and stored in a list called dependents. Additionally, a list called head nodes is created and a ROOT node is added. At the final stage, the dependency tree is created according to the following algorithm:

- while dependents is not empty
  1. remove first token
  2. assign a head from head nodes:
     - if universal dependency rules (Naseem et al., 2010) are used: assign the closest head (in terms of distance in the sentence) for which a rule fires
     - else, or if no rule applies: assign the closest head candidate

4 Extensions

In this section, we describe all the extensions we will apply in order to achieve improvements for the parsing.

4.1 Re-running the Parsing

We expect that dependencies produced by the unsupervised parser might be helpful also for the parsing. Thus, we first apply Søgaard’s parser to a new sentence. Then, we add the detected syntactic dependencies as weights to the normal heuristics, apply the ranking and build the dependency tree again.

4.2 Learning Regularities

One main advantage of Søgaard’s parser is that it does not require any training since it applies a collection of heuristics. However, previous decisions provide valuable information about the relationship of various POS. In order to utilize this information, we apply Søgaard’s parser on raw text and use the dependency labels as training data for the Malt-Parser (Nivre, 2008). Using this model, we parse the test data and perform the evaluation on these dependencies.

4.3 Integrating Semantics

Words that have a similar meaning are usually on a similar level of salience. Therefore, we experimented removing edges between neighboring tokens that have a distributionally similar meaning. We use similarities computed with the approach by Biemann and Riedl (2013). As context representation we use the so-called trigram context extraction method, which uses the left and right neighboring word as context. In addition, we show results for German and English when using similarities computed using syntactic dependencies from a supervised method as context.

4.4 Integrating Multiword Expressions

Recognizing MWEs is beneficial for parsing, cf. Le Roux et al. (2014). Thus, we add edges between words that are recognized as MWEs according to a generated list of MWEs. This resource is generated using the unsupervised word sequence ranking measure called DRUID (Riedl and Biemann, 2015).
The measure does not require any POS filtering and can be applied to corpora without any linguistic pre-processing. We computed DRUID on a larger background corpus and used only word sequences of a maximum length of 4 and a score above 0.5. If a token was part of the same MWE as a head candidate, we preferred that candidate in the same vein as if it would match a universal rule.

5 Experimental Setting

We evaluate on German, Danish, Dutch, Portuguese, and Swedish test data from the 2006 CoNLL shared task on multi-lingual dependency parsing. For English, we evaluated on Section 23 of the Wall Street Journal part of Penn Treebank III (PTB-III). As development set we use Section 11 of PTB-III. The treebank was converted to dependencies using the LTH Constituent-to-Dependency converter. We train the MaltParser based on the parser’s output on the train data of Danish, Dutch, German, Portuguese and Swedish. For English, we used the entire Wall Street Journal section of PTB-III. Unlabeled attachment scores were obtained using the official CoNLL-07 scorer.

For computing the similarities and the MWE resource for English we use 105M sentences of newspaper extracted from the Leipzig Corpora Collection (LCC) (Richter et al., 2006) and Gigaword (Parker et al., 2011). The computations for German are performed on 70M sentences from the LCC; for Swedish 60M sentences of newspaper data from Språkbanken are used. For Dutch, we compute similarities and MWEs based on 259 million sentences from the Dutch web corpus (Schäfer and Bildhauer, 2013). The Portuguese is computed based on the Brazilian web corpus (Boos et al., 2014).

The dependency-based similarities are computed using the Stanford Parser (de Marneffe et al., 2006) for English and the MaltParser (Nivre, 2008) for German.

6 Results

In this section, we show the result of our re-implementation and additionally show the performances on different languages when incorporating the different modifications.

6.1 Performance on several languages

The results with our implementation are presented for the six languages in Table 1, next to the results from Søgaard (2012).

</table>

Table 1: Basic unlabeled attachment scores on sentences with at most 10 tokens without punctuation. UR: Universal dependency rules enabled.

For unknown reasons, we cannot replicate results reported in (Søgaard, 2012). Whereas for Danish and Dutch, we observe higher scores than the ones in the paper, most results are below the performance of Søgaard (2012). This finding is consistent for both using universal dependency rules (URs) and without using URs. In accordance with the original implementation, our re-implementation outperforms the right-branching baseline. Like Søgaard (2012), we considered as upper bound an oracle function that ranks tokens in a top-to-bottom, left-to-right fashion according to their gold dependency trees.

6.2 Performance of Extensions

In this section, we describe the performance of the various extensions for adding edges into the graph-based method. First, we show results in Table 2 when re-running the algorithm, using dependency links from the first pass as additional edges. The number of additional edges (6) was determined using the English development data.

We observe that this extension reduces the performance both for Danish and Dutch tremendously. However, for English we observe significant improvements both for using/not using universal dependency rules. For German and Portuguese we only observe improvements when using universal

---

The implementation is available under the Apache 2.0 license: http://jobimtext.org/jobimtext/components/unsupervised-parser

Although we also tested the original implementation, we could not achieve the results from the paper. This might be attributed due to different keyword lists and different corpus transformations.
dependency rules. Thus, no general trend can be obtained for re-using unsupervised dependency information.

Next, we show results in Table 3 when using the links obtained with Søgaard’s dependency parser in order to train the supervised MaltParser as described in Section 4.2. Except for Danish, this approach consistently yields improvements. This changes when universal rules are used; here, the performance on Dutch and Danish increases. For English we significantly outperform the basic results. However this comes at the cost of losing the runtime benefit of Søgaard’s parser.

Next, we present the impact when integrating semantic information and MWE information into the unsupervised parser. As can be obtained from Table 4, using semantic information that is computed on neighboring words decreases the performance for all languages but Portuguese. Applying these rules, we observe declines for Dutch and Swedish, but gain improvements for the remaining languages. Additionally, we tested similarities for English and German that are computed using syntactic dependencies as context representation for testing purposes, as it defies the goal of inducing a parser for languages without treebank resources. Without using universal rules, we observe a decrease in terms of performance for English (43.25) and obtain slight increases for German (45.22).

Integrating information from the MWE resource and not applying the universal rules results in consistent yet small improvements among all tested languages (see Table 4). Similar to the results using semantic information, scores increase for all languages except for Dutch when using universal rules.

In the next experiment, we combined several extensions. As can be observed from Table 5 integrating semantic and MWE information improves the performance in all cases except for Swedish. In addition we also present results when adding the re-running to the algorithm. For Dutch and Swedish we notice a performance decline. When using universal rules, we observe an increase in performance for English, German, and Portuguese.

7 Conclusion

In this paper we have shown that intuitive and reasonable extensions for Søgaard’s dependency parser do not translate into general improvements among all languages. This is in line with the findings described in (Riedl et al., 2014) that most unsupervised dependency parsers are optimized for English rather than the other languages. Whereas some extensions yield minor improvements, we cannot give any language-independent recommendation.

Table 2: Results for re-running the algorithm on the same sentence. Scores with a † are significant over the basic score (paired bootstrap resampling test (Koehn, 2004) with $p = 0.05$, $n = 1000$).
